## What is functional programming?

- Functions are first class (objects).
  - That is, everything you can do with "data" can be done with functions themselves (such as passing a function to another function).
- Recursion is used as a primary control structure.
  - In some languages, no other "loop" construct exists.
- There is a focus on list processing.
  - Lists are often used with recursion on sub-lists as a substitute for loops.
- "Pure" functional languages eschew side-effects.
  - This excludes assignments to track the program state.
  - This discourages the use of statements in favor of expression evaluations.

## Whys

- All these characteristics make for more rapidly developed, shorter, and less bug-prone code.
- A lot easier to prove formal properties of functional languages and programs than of imperative languages and programs.

# Functional Programming in Python

## map(), filter() & reduce()

Python has functional capability since its first release

- with new releases just a few syntactical sugar has been added

Basic elements of functional programming in Python are:

- **map()**: it applies a function to a sequence

```
>>> import math, functools
>>> print(list(map(math.sqrt, [x**2 for x in range(1,11)])))
[1.0, 2.0, 3.0, 4.0, 5.0, 6.0, 7.0, 8.0, 9.0, 10.0]
```

- **filter()**: it extracts from a list those elements which verify the passed function

```
>>> def odd(x): return (x%2 != 0)
>>> print(list(filter(odd, range(1,30))))
[1, 3, 5, 7, 9, 11, 13, 15, 17, 19, 21, 23, 25, 27, 29]
```

- **reduce()**: it reduces a list to a single element according to the passed function

```
>>> def sum(x,y): return x+y
>>> print(functools.reduce(sum, range(1000)))
499500
```

Note, **map()** and **filter()** return an iterator rather than a list.

### Short-Circuit Conditional Calls instead of **if**

```
def cond(x):  
    return (x==1 and 'one') or (x==2 and 'two') or 'other'  
  
if __name__ == "__main__":  
    for i in range(3):  
        print("cond({0}) :- {1}".format(i, cond(i)))
```

```
[17:34]cazzola@hymir:~/esercizi-pa>python3 fcond.py  
cond(0) :- other  
cond(1) :- one  
cond(2) :- two
```

### Doing some abstraction

```
block = lambda s: s  
cond = \  
    lambda x: \  
        (x==1 and block("one")) or (x==2 and block("two")) or (block("other"))  
  
if __name__ == "__main__":  
    print("cond({0}) :- {1}".format(3, cond(3)))
```

```
[17:55]cazzola@hymir:~/esercizi-pa>python3 fcond.py  
cond(3) :- other
```

## Do Abstraction: Lambda Functions

The name lambda comes from  $\lambda$ -calculus which uses the Greek letter  $\lambda$  to represent a similar concept.

Lambda is a term used to refer to an **anonymous function**

- that is, a block of code which can be executed as if it were a function but without a name.

Lambdas can be defined anywhere a legal expression can occur.

A Lambda looks like this:

**lambda** “args”: “an expr on the args”

Thus the previous **reduce()** example could be rewritten as:

```
>>> import functools
>>> print(functools.reduce(lambda i,j: i+j, range(1000)))
499500
```

Alternatively the lambda can be assigned to a variable as in:

```
>>> add = lambda i,j: i+j
>>> print(functools.reduce(add, range(1000)))
499500
```

### Traditional implementation

```
def fact(n):  
    return 1 if n<=1 else n*fact(n-1)
```

### Short-circuit implementation

```
def ffact(n):  
    return (n<=1 and 1) or n*ffact(n-1)
```

### reduce()-Based implementation

```
from functools import reduce  
def f2fact(p):  
    return reduce(lambda n,m : n*m, range(1,p+1))
```

Sequential program flow is typical of imperative programming

- it basically relies on side-effects (variable assignments)

This is basically in contrast with the functional approach.

In a list processing style we have:

```
# let's create an execution utility function
do_it = lambda f: f()

# let f1, f2, f3 (etc) be functions that perform actions
map(do_it, [f1,f2,f3])    # map()-based action sequence
```

- single statements of the sequence are replaced by functions
- the sequence is realized by mapping an activation function to all the function objects that should compose the sequence.

### Statement-Based echo function

```
def echo_IMP():  
    while True:  
        x = input("FP -- ")  
        if x == 'quit': break  
        else: print(x)  
if __name__ == "__main__": echo_IMP()
```

### First step toward a functional solution

- No print
- Utility function for "identity with side-effect" (a monad)

```
def monadic_print(x):  
    print(x)  
    return x
```

### Functional version of the echo function

```
echo_FP = \  
    lambda: monadic_print(input("FP -- "))=='quit' or echo_FP()  
if __name__ == "__main__": echo_FP()
```

```
[10:12]cazzola@hymir:~/esercizi-pa>python3 fecho.py  
FP -- walter  
walter  
FP -- quit  
quit
```

Why? To eliminate the side-effects

- mostly all errors depend on variables that obtain unexpected values
- functional programs Bypass the issue By not assigning values to variables at all.

E.g., To determine the pairs whose product is >25.

```
def bigmuls(xs,ys):  
    bigmuls = []  
    for x in xs:  
        for y in ys:  
            if x*y > 25:  
                bigmuls.append((x,y))  
    return bigmuls  
  
if __name__ == "__main__":  
    print(bigmuls((1,2,3,4),(10,15,3,22)))
```

```
[22:03]cazzola@hymir:~/>python3 fbigmuls.py  
[(2, 15), (2, 22), (3, 10), (3, 15),  
 (3, 22), (4, 10), (4, 15), (4, 22)]
```

```
from functools import reduce  
import itertools  
  
bigmuls = \  
    lambda xs, ys: \  
        [x_y for x_y in \  
            combine(xs,ys) if x_y[0]*x_y[1] > 25]  
combine = \  
    lambda xs, ys: \  
        itertools.zip_longest(\  
            xs*len(ys), dupelms(ys,len(xs)))  
dupelms = \  
    lambda lst, n: \  
        reduce( \  
            lambda s, t: s+t,  
            list(map(lambda l,n=n: [l]*n, lst)))  
  
if __name__ == "__main__":  
    print(bigmuls([1,2,3,4],[10,15,3,22]))
```

# Functional Programming in Python

## Future of map(), reduce() & filter()

The future of the Python's **map()**, **filter()**, and **reduce** is uncertain.

Comprehensions can easily replace **map()** and **filter()**

- **map()** can be replaced by

```
>>> import math
>>> [math.sqrt(x**2) for x in range(1,11)]
[1.0, 2.0, 3.0, 4.0, 5.0, 6.0, 7.0, 8.0, 9.0, 10.0]
```

- **filter()** can be replaced by

```
>>> def odd(x): return (x%2 != 0)
>>> [x for x in range(1,30) if odd(x)]
[1, 3, 5, 7, 9, 11, 13, 15, 17, 19, 21, 23, 25, 27, 29]
```

Guido von Rossum finds the **reduce()** too cryptic and prefers to use more ad hoc functions instead

- **sum()**, **any()** and **all()**

To have moved **reduce()** in a module in Python 3 should render manifest his intent.
